Region-Support Depth Inference from a Single Image

Anonymous CVPR submission

Paper ID ****

Abstract

challenge in the computer vision community. It is techni-

cally ill-posed since monocular cues like the scale ratio or

the objects variance are ambiguous for inference of depth.

In this paper, we propose the region support as the infer-

ence guidance to resolve the ambiguity. The region sup-

port is the regional segmentations each of which consists of

pixels at similar depths. It formulates the depth inference

working in two steps: first inferring the regional depth and

then refining the regional depth to pixel-wise depth. The

region-support depth inference is realized a novel network

consisting of three modules: generation of region support,

computation of regional depth and regional refinement to

pixel-wise depth. We first obtain the region support by a

novel clustering-based segmentation module and then use

the obtained region support as additional channel to infer

the initial pixel-wise depth, where the two modules share

the same multi-scale feature from a pyramid unit. Then we

use the region support as masks on the initial pixel-wise

depth to compute the regional depth. The regional refine-

ment to pixel-wise depth separately works on the initial

pixel-wise depth map by the target refinement and on the

regional depth map by the variance refinement. The tar-

get refinement makes the depth among each region close to

its stable mean depth while the variance depth models the

variance on the basis of the mean depth of each region. The

final refined depth map fuses the output of both refinements.

From the experiments on the NYU and KITTI datasets, we

can see both the regional depth and the two-steps regional

refinement can remarkably reduce the ambiguity and raise

The depth estimiation methods can be widely used in

robotics, autonomous vehicles, recognition tasks, visual lo-

calization and scene analysis [11, 4, 1, 5]. As monocular

images are the most readily available data, the depth in-

ference from a single image has attracted considerable at-

the inference accuracy.

1. Introduction

Depth inference from a single image is a long-standing

RGB

Semantic

wise depth.

Depth

Instance

tion beween different depth but same labels.

Figure 1. The comparison of regional guidances. In the red boxes,

we can see the semantic guidance has conflicts with the different

depth of the 'light'. In the blue box, we can see both the instance

and the semantic guidance cannot offer supportive guide of the

'wall' which varies a lot on the depth. The SLIC guidance over-

segments objects too much, which makes the regional guidance

too sensitive to adapt different scenes. As for our region support,

we can see it ensures the supportive information from the semantic

and instance guidance meanwhile resolves the ambiguitous situa-

tention in the past decades [15, 3, 18]. It mostly relies on

monocular cues like the scale ratio, feature variance of ob-

jects and so on [3, 9], but these cues are ambiguous to guide

the depth inference. Many strategies have been proposed

to resovle the ambiguous problem, for example, using the

additional supportive guidance like semantic information to

guide the inference [17, 10, 20], discretizing the continuous

depth into interval values to regularize the inference space

[14], using the coarse-to-fine framework to arrange the in-

ference and so on. In this paper, we propose the region

support as the guidance for the depth inference and design

a novel region-support depth inference network which re-

alizes the depth inference by two stages: infering the re-

gional depth and refining the regional depth to the pixel-

regions each of which consists of pixels at similar depths.

Like many regional guidances, it guides the inference by the

assumption that with the same regional label, the variance

of depth should be stable and continuous. However, most

regional guidance can not truely realize this assumption, as

The region support is a special kind of segmentation of

shown in Figure 1, the semantic guidance has problem in the red box where the 'lights' are at different depth but has the same semantic label. Besides, in the blue box, objects like 'wall' cross a long range of depth but the label is the same for the region. As for the super-pixel based approaches, the division of regions is too sensitive to adapt for different scenes. Compared with these guidance, the region support can effectively handle the above ambiguious situations.

135 We use the region support to formulate the depth in-136 ference working in two steps: infering the regional depth 137 and refining to the pixel-wise depth. As shown in Figure 138 2, we design the region-support depth inference network to 139 carry out this two-steps formulation, which consists of three 140 modules: generation of the region support, computation of 141 the regional depth and regional refinement to the pixel-wise 142 depth. To generate the region support, we design a novel 143 clustering-based segmentation module which consists of the 144 pyramid feature extraction unit and the learnable clustering 145 segmentation unit. The pyramid unit provides the multi-146 scale feature as the representation and then the clustering 147 unit takes into the multi-scale feature to generate the region 148 support by the clustering-based segmentation like [2, 13]. 149 Then we combine the shared feature with the region sup-150 port to infer the pixel-wise initial depth through several con-151 volutional layers. The region support serves as masks for 152 the initial depth to compute the mean depth of each region, 153 meanwhile the masks are applied to the shared feature to 154 compute the regional feature map. 155

The regional refinement is conducted by the variance refinement and target refinement. The variance refinement refines the regional depth by learning the variance on the mean depth of each region while the target refinement refines the initial depth to close to its mean depth of each region. The outputs of the two refinement sub-modules fuses with each other to form the final depth map. A unified loss function is proposed to ensure the end-to-end training, which consists of the discriminative loss for the clustering segmentation and berhu loss for the refinement module. For the data without regional labels, we design a novel semisupervised loss which only uses the depth as supervision to train the clustering module.

Variance

Refinement

Targe

The region-support depth inference method reaches state-of-the-art performance on the NYUv2 [12, 16] and KITTI [5] datasets. From the alation analysis, we can see both the formulation of the regional depth and regional refinement can effectively resolve the ambiguities and constraint the depth inference space. Our contribution can be summarized in three folds:

- We propose the region support as the guidance for the depth inference from a single image, which formulates the depth inference as the infering of regional depth and refining the regional depth to pixel-wise depth.
- We design a novel region-support depth inference network with three modules: the generation of region support, the computation of the regional depth and regional refinement to pixel-wise depth. A unified loss for each module is designed for the end-to-end training with a novel discriminative loss for the clusteringbased segmentation.
- The region-support depth inference reaches the stateof-the-art performance on challenging datasets. Both the formulation of the regional depth and regional refinement are proven to be effective to simplify the depth inference.

216 2. Related Work

There are many strategies to resolve the ambiguities dur-218 219 ing the depth inference while the most related three strate-220 gies to our method is using the semantic guidance, coarse-221 to-fine formulation and discretizing the continuous depth 222 into intermediate depth. Many works found that combin-223 ing the semantic segmentation task with the depth inference 224 can improve the performance for both tasks. Mostly the in-225 tergration of the semantic segmentation and depth inference 226 are realized by the concatenation operation which treats the semantic segmentation as additional guidance for the infer-227 228 ence. Then the two tasks could be jointly optimized by the 229 end-to-end training with the multi-task loss. This kind of 230 strategy can reach sufficient performance benefiting from 231 the learnable usage of guidance from the joint optimiza-232 tion, however, the semantic guidance has its natural con-233 flicts with depth. Therefore, we propose the region support 234 to release the conflicts between regional guidance and true 235 depth. In addition, we form a much more explicit usage of 236 regional guidance by using the region support to form the 237 regional depth and regional refinement.

238 The coarse-to-fine strategy is a widely used strategy for 239 depth inference task, which seperates the inference process 240 into two steps: computing the coarse depth and refining the 241 coarse depth to the fine. Many methods built a two-stages 242 network to realize this strategy with different approaches to 243 compute the coarse depth or refine the coarse depth. Some 244 works contributed on the computation of coarse depth by 245 designing a more effective network to extract the multi-246 scale feature, while others foucs on the post-processing like 247 the conditional random field (CRF) and iterative optimiza-248 tion to enhance the refinement module. Compared with 249 these methods, we define the coarse depth as the regional 250 depth and design the variance and target refinement to ob-251 tain the pixel-wise depth from the regional depth. Current, 252 discretizating the continious depth into discrete intermedi-253 ate depth shows ability to resolve the ambiguities by trans-254 forming the regression of depth into the classification of dis-255 crete ranges of depth. The regional depth formulation can 256 be deemed as a special discretization which is more adap-257 tive than the constant discretized ranges. Since the discrete 258 ranges changes for different scenes, we use the region sup-259 port to adaptively discrete the continuous depth into the dis-260 crete regional depth and then refine this discrete depth to 261 continuous depth. 262

3. Region-Support Depth Inference

263

264

As shown in Figure 2, the region-support depth inference network has three modules: the generation of region support, the computation of regional depth and the regional refinement to pixel-wise depth. All of these modules share the multi-scale feature from a spatial pyramid unit which consists of 34 residual layers and a spatial pooling layer. The generation of region support module uses 2D convolutional layers to generate the clustering feature from the shared feature and uses a clustering-based segmentation approach to generate the region support. The computation of regional depth module first combines the shared feature with the obtained region support to infer the initial depth and then use the obtained region support as masks to compute the regional coarse depth. The regional refinement module seperately works as the variance refinement on the regional depth and the target refinement on the initial depth. We fuse the outputs of these two refinements to form the final depth map. All of the three modules can be trained end-to-end by a unified loss function for the clustering segmentation and the regional refinement.

3.1. Generation of Region Support

3.1.1 Spatial Pyramind Unit

We adopt a spatial pyramid architecture to utilize multiscale features for the determination of the region support. A standard ResNet [7] with 4, 10, 5, 5 basic residual blocks is applied as the feature extraction. We conduct the subsampling on the second and third block, so we get a subsampled feature map with the 1/4 resolution size after the residual layers. Then we employ the spatial pyramid pooling unit [19] to enhance the multi-scale features by pooling the feature map into four lower scales, i.e., 1/8, 1/20, 1/80and 1/240. The sub-sampled feature maps respectively pass through one convolutional layer with 1/4 input channel. After that, the sub-sampled feature maps are resized into the 1/4 resolution size by bilinear interpolation and concatenated together with the 1/4 resolution residual feature map. To fuse the multi-scale feature, we adopt two de-convolutional units each of which has three layers: one convolutional layer before the de-convolutional layer and one after the de-convolutional layer. The concatenation skip connection is used between the up-sampled feature map and the previous feature map from the output of the first and second residual block.

3.1.2 Clustering Segmentation

The region support is determined by the depth distribution of the pixels, so it is quite different from the semantic or instance segmentation. Besides, the label for each region can not be strictly corresponding to a constant depth value because the direct inference of the absolute depth for each region is as difficult as infering the pixel-wise depth. So the label for the region support can only reveal whether the pixels are at similar depth but do not represent the real depth. The common detection based approaches like R-CNN or Mask-RCNN is not useful for this task since the labels vary dynamically for different scenes. Inspired by the BrabanCVPR

der et al. [2] and Novotny et al. [13], we find out that the clustering-based segmentation can satisfy the dynamical labeling task since the label can be determined by the distribution of the feature itself.

342 The shared multi-scale feature map first concatenates 343 with the two-channel location map to form the fused fea-344 ture, which is different from the add operation in [13]. Then 345 four convolutional layers are used to refine the fused map 346 and adjust the channel to 16 to release the computational re-347 source for the clustering. We design a modified mean-shift 348 clustering unit to obtain the segmentation from the refined 349 feature map which is shown in the Algorithm 1. Compared 350 with the common mean shift approach, we only shift the clustering center for twice to save the time for segmentation 351 352 and add the fusion part to get a more stable division. Al-353 though this clustering unit is fully differencial, it is not in-354 volved into back-propogation because it will cost too much 355 memory due to the iterative clustering. To make this part 356 trainable, we propose the supervised and semi-supervised 357 loss.

Supervised and Semi-supervised Discriminative 3.1.3 Loss

The discriminative loss function for the clustering-based segementation is formulated as the pull and push forces between and within clusters [2]. The pull force is realized by penelizing the intra-cluster variance, which can be indicated like

$$L_{var} = \frac{1}{C} \sum_{c=1}^{C} \frac{1}{N_c} \sum_{p=1}^{N_c} \left[\|\mu_c - F(p)\| - \delta_v \right]_+^2 \quad (1)$$

371 Here, C is the number of regions, N_c is the number of pixels 372 in region c, μ_c is the mean feature of region c and F is the fused feature map. $\|\cdot\|$ is the L_1 distance and $[x]_+$ is the 373 max(x,0) function. The variance loss makes the embed-374 375 ding of same region close the mean feature of this region 376 while the δ_v is the maximum variance for each cluster. The 377 push force is realized by the distance loss which is shown

as

experiments.

$$L_{dist} = \frac{1}{C(C-1)} \sum_{\substack{c_A=1\\c_A\neq c_B}}^{C} \sum_{c_B=1}^{C} \left\lceil 4\delta_v - \|\mu_{c_A} - \mu_{c_B}\| \right\rceil_+^2$$

383

(2)The distance loss pushes the clusters away from each other and at least has a distance of $4\delta_v$ between two cluster centers. The final discriminative loss $L = L_{var} + L_{dist}$ is similar to the loss function for general instance segmentation [2, 13]. Novotny et al. [13] found directly minimizing the inner variance can reach better performance, but we need the variance δ_v to employ the Algorithm 1, so we still use the clap version as [2] but with a dynamical δ_v . In our experiments, the δ_v is first set by 0.16 and the updated after each training step as $\delta_v = \lambda \times \delta_v + (1 - \lambda) \times \sum_{c=1}^{C} \delta_c$, where δ_c is the variance in region c and λ is set by 0.99 in our

For the data only having depth supervision D, we propose the semi-supervised loss. We first use the Algorithm 1 to obtain the region support and then compute the mean depth for each region. After that, we can get the variance for each pixel. We assume that if the variance is more than δ_d which is empirically set as the $\frac{\max(D) - \min(D)}{20}$, this pixel is clustered in the wrong area. So the regions can be divided as two sub-sets R and W which are the right division and wrong division. For the right division, we want the feature of the pixels are more close to the cluster center, while for the wrong division, we want these pixel move away from the cluster center. We design the L_{wr} to realize the pull and push force which can be expressed as

$$L_{rw} = L_r + L_w,\tag{3}$$

$$L_r = \frac{1}{R} \sum_{r=1}^{R} \frac{1}{N_r} \sum_{p=1}^{N_r} \left[\|\mu_r - F(p)\| - \delta_v \right]_+^2, \quad (4)$$

$$L_{w} = \frac{1}{W} \sum_{w=1}^{W} \frac{1}{N_{w}} \sum_{p=1}^{N_{w}} \left\lceil 2\delta_{v} - \|\mu_{r} - F(p)\| \right\rceil_{+}^{2}.$$
 (5)

When the L_{rw} becomes zeros, all of the pixels are within a distance of δ_v to its cluster center while at least $2\delta_v$ from the other cluster center. So we can simply use the Algorithm 1 to get the region support.

3.2. Computation of Regional Depth

The computation of regional depth works in two steps where we first compute the initial pixel-wise depth and then compute the mean depth for each region as the regional depth. We adopt four residual units to reduce the channel of the shared feature and then use three common convolutional units to infer the initial depth for each pixel, where

4

the final inference layer output the one channel depth map. Then we use the obtained region support as masks to com-pute the mean depth for each region. Since there are unla-beled pixel if the number of regions becomes more than 80, these unlabed pixels can not be used to compute the regional depth, so we only use the initial depth as the regional depth for there unlabeled pixels. At the same time, we also use the region support as masks on the shared feature to com-pute the regional feature as the supportive information for the refinement module

3.3. Regional Refinement

The regional refinement works as the variance refine-ment and the target refinement. The variance refinement computes the variance of the mean depth value to infer the exact depth for each pixel. We combine the regional depth with the shared feature and the regional feature map as the input for the variance refinement. The variance refinement module consists of five convolutional units where the last unit removes the Relu and the Normalization layer. Then the regional depth adds the output to form the refined re-gional depth. As for the target refinement, it shares the structure of the variance refinement but with the combina-tion of initial depth, regional feature and shared feature as input. The output adds the initial depth map to form the re-fined result. The target refinement computes the variance of the initial depth for each pixel with regarding to the mean dpeth of its region. The final depth map fuses the two re-fined depth where we use a very simple average fusion in this paper.

A behu loss [8] is adopted to train the refinement module which can be indicated as

$$L_{d} = \begin{cases} \left| \log(d) - \log(d') \right| & \left| \log(d) - \log(d') \right| \le \delta_{d} \\ \frac{\left\| \log(d) - \log(d') \right\| + \delta_{d}^{2}}{2\delta_{d}} & \left| \log(d) - \log(d') \right| > \delta_{d} \end{cases}$$
(6)

Here, the *d* is the ground truth depth, d' is the predicted depth, $|\cdot|$ is the L_1 distance, $||\cdot||$ is the L_2 distance and $\delta_d = \frac{1}{5}max(log(d_p) - log(d'_p))$.

3.4. Implementation Details

All of the convolutional and residual layers are followed by the GroupNorm with group num 1 and ReLU unit except for the last layers of the two refinement sub-modules. We adopt the duplication padding for all of the convolutional operation. We use the nearest interpolation for the spatial pyramid pooling unit. The kernel size for the last three layers of the two refinement and the 14 layer is set to 1×1 while the deconvolutional layers have the 4×4 kernel size.
